Neuronal Activity Promotes Oligodendrogenesis and Adaptive Myelination in the Mammalian Brain

Erin M. Gibson, David Purger, Christopher W. Mount, Andrea K. Goldstein, Grant L. Lin, Lauren S. Wood, Ingrid Inema, Sarah E. Miller, Gregor Bieri, J. Bradley Zuchero, Ben A. Barres, Pamelyn J. Woo, Hannes Vogel, Michelle Monje*

**Introduction:** Myelin is formed by mature oligodendrocytes to facilitate fast propagation of action potentials in axons. Small changes in myelin thickness can confer substantial changes in conduction speed and may thus alter neural circuit function. The idea that active neurons may modulate myelination is supported by in vitro studies and correlations between experience and myelin microstructure, but direct in vivo evidence demonstrating that neuronal activity regulates oligodendrocyte precursor cell (OPC) proliferation, differentiation, or changes in myelin microstructure has been lacking. We use in vivo optogenetic techniques in awake, behaving mice to provide direct evidence that neuronal activity regulates changes in myelin-forming cells within an active circuit.

**Rationale:** Demonstrating the direct effects of behaviorally relevant neuronal activity on oligodendroglial lineage cells in vivo has been a challenge because traditional methods of directly promoting neuronal activity involve placement of an electrode, and the resultant tissue injury and subsequent inflammation affects OPC dynamics. Optogenetic technology allows for in vivo control of neuronal firing with millisecond precision using light delivered at a distance from the target and, thus, avoids extensive electrode-related tissue damage. We used an optogenetic (Thy1::ChR2) mouse model in which 470-nm light delivered near the brain surface stimulates the excitatory opsin channelrhodopsin expressed by cortical layer V projection neurons. Wild-type littermate controls lacking channelrhodopsin were identically manipulated to control for effects of surgery, optical fiber placement, and light exposure. In Thy1::ChR2 mice, light stimulation delivered unilaterally to the premotor cortex elicits complex motor behavior (unidirectional ambulation). The thymidine analog 5-ethyl-2'-deoxyuridine (EdU) was administered at the time of optogenetic stimulation to mark actively dividing cells. Animals were evaluated at various time points to examine the effects of neuronal activity on myelin-forming cells and myelin microstructure, as well as the functional consequences of neuronal activity–regulated myelin changes.

**Results:** Optogenetic stimulation of cortical layer V projection neurons resulted in robust proliferation of OPCs within the premotor circuit, from the deep layers of the premotor cortex to the subcortical projections through the corpus callosum. Four weeks later, an increase in newly generated oligodendrocytes and increased myelin sheath thickness were found within the stimulated premotor circuit. Behavioral testing revealed increased swing speed of the correlate forelimb. Pharmacological blockade of OPC differentiation prevented activity-regulated oligodendrogenesis and myelin changes, as well as the associated behavioral change.

**Conclusion:** Neuronal activity regulates OPC proliferation, differentiation, and myelin remodeling in the murine brain with accompanying changes in behavioral function. Taken together, these findings suggest that adaptive changes in myelin-forming cells represent a type of behaviorally relevant neural plasticity, raising numerous conceptual and mechanistic questions. Mechanisms regulating myelin plasticity may be important for adaptive neural function and could be leveraged for interventions in diseases of myelin. Conversely, dysregulated myelin plasticity could conceivably contribute to disease.
Neuronal Activity Promotes Oligodendrogenesis and Adaptive Myelination in the Mammalian Brain

Erin M. Gibson, David Purger, Christopher W. Mount, Andrea K. Goldstein, Grant L. Lin, Lauren S. Wood, Ingrid Inema, Sarah E. Miller, Gregor Bieri, J. Bradley Zucher, Ben A. Barres, Pamelyn J. Woo, Hannes Vogel, Michelle Monje

Myelination of the central nervous system requires the generation of functionally mature oligodendrocytes from oligodendrocyte precursor cells (OPCs). Electrically active neurons may influence OPC function and selectively instruct myelination of an active neural circuit. In this work, we use optogenetic stimulation of the premotor cortex in awake, behaving mice to demonstrate that neuronal activity elicits a mitogenic response of neural progenitor cells and OPCs, promotes oligodendrogenesis, and increases myelination within the deep layers of the premotor cortex and subcortical white matter. We further show that this neuronal activity–regulated oligodendrogenesis and myelination is associated with improved motor function of the corresponding limb. Oligodendrocygenesis and myelination appear necessary for the observed functional improvement, as epigenetic blockade of oligodendrocyte differentiation and myelin changes prevents the activity-regulated behavioral improvement.

Development of the myelinated fiber infrastructure of the brain occurs throughout childhood and young adulthood and is classically thought to complete when the frontal lobes finish myelin formation in the fourth decade of human life (1, 2). Maturation of the complex neural circuitry necessary for high-level cognitive and motor functions depends on myelination, the process by which oligodendrocytes ensheathe and insulate axons to facilitate fast, salutary conduction of electrical impulses. Whereas the protracted nature of neocortical myelination is well recognized, the mechanisms governing myelination after infancy remain largely unknown (3–5).

An intriguing but unproven possibility is that postnatal myelination may be modulated by mature neurons to augment an active circuit. The idea that excitatory neuronal activity instructs myelination, including oligodendrocyte precursor cell (OPC) proliferation, differentiation, and myelin biosynthesis, is supported by multiple lines of evidence. Blockade of activity in the developing optic nerve by axotomy or tetrodotoxin decreases OPC proliferation (5); myelination in vitro is activity-dependent (6–9); and some data suggest that OPC proliferation, differentiation, or the rate of myelin development in vivo is enhanced by nonphysiological (333 Hz) or pathological perturbations of electrical activity (10, 11). Further supporting the idea that excitatory neuronal activity may influence OPC behavior, neurons form glutamatergic synaptic connections onto OPCs (12–17). However, an elegant study conditionally ablating a necessary subunit of the N-methyl-D-aspartate (NMDA) receptor in oligodendroglial lineage cells during development did not demonstrate deficits in oligodendrogenesis or myelination, arguing against a role for direct NMDA receptor-mediated axoglial synaptic neurotransmission as a mechanism regulating myelination in vivo (18). The potential role of neuronal activity in the regulation of myelin-forming cells remains unclear in vivo; if established, this would constitute a previously underestimated mechanism by which experience directs adaptive behavioral change.

Results

Description of the Optogenetic Model and Experimental Paradigm

In this work, we used optogenetic stimulation of the premotor cortex in awake, behaving Thy1::channelrhodopsin 2 (ChR2) mice (19, 20) to test the effects of neuronal activity on oligodendroglial cells in vivo. In this well-characterized model, the excitable opsin is expressed in a subset of neurons under the control of the Thy1 promoter. In the cortex, the Thy1 promoter and, thus, the excitable opsin are expressed chiefly in cortical layer V projection neurons and are not expressed in glial cell types (19, 20). ChR2-expressing neurons respond to pulses of blue (470-nm) light with millisecond precision such that the frequency of light pulses elicits neuronal spiking of the same frequency (19, 20). Expression of ChR2 does not alter the electrical properties of neurons in the absence of blue light and does not affect neuronal survival under basal conditions or with blue light stimulation using standard experimental parameters (21). When the optical fiber is placed just below the pial surface, ~10% of the blue light penetrates 0.5 mm, or about halfway through the cortex, and ~1% reaches 1 mm (to cortical layer VI) (22). This stimulates the apical dendrites of layer V neurons and, to a lesser extent as the light is attenuated by layer V, the neuronal somata, resulting in neuronal firing of layer V projection neurons (22). Heat generated by this system is negligible under these conditions and localized to the optical fiber (22).

Stimulation from just below the pial surface limits hardware-related injury to the skull and cortical layer I, in contrast to alternative strategies such as intracortical microstimulation that involve more extensive electrode-related tissue damage.

We placed the optical-neural interface just below the pial surface in cortical layer I of area M2 (premotor area) (Fig. 1A) in juvenile [postnatal day 35 (P35)] mice and stimulated unilaterally with blue light for 30-s intervals every 2 min over a 30-min period at 20 Hz, a frequency consistent with the 10- to 40-Hz physiological firing rates of layer V projection neurons in the motor cortex (19). Unilateral stimulation of right-sided M2, a high-level cortical region involved in motor planning and the generation of complex and goal-directed motor behavior (23), caused mice to ambulate consistently in the contralateral (left) direction when the blue light was on (movie S1). This behavioral measure confirms proper placement of the light-stimulation fiber and demonstrates the expected behavioral consequences of optogenetic premotor cortex stimulation. The placement of the fiber requires breaking the skull and dura, and the fiber penetrates the most superficial layer of the cortex (layer I). Because injury (24) and the associated microglial inflammation (25) can influence OPC behavior, wild-type ([WT), no opsin present] littermate control animals were instead manipulated to control for effects of surgery, fiber placement, and light. In WT mice, blue light stimulation causes no observable change in behavior. We used manipulated WT littermate controls in all analyses described below to account for effects of injury and inflammation.

Neuronal Activity–Regulated Precursor Cell Proliferation

To test the acute effects of neuronal activity on cell proliferation, we administered the thymidine analog 5-ethyl-2′-deoxyuridine (EdU) at the beginning of the 30-min stimulation period to label dividing cells and sacrificed mice 3 hours later. Following this period of activity, we observed a proliferative response in the premotor...
cortex (Fig. 1, A and B) and subcortical white-matter projections in the corpus callosum (Fig. 2). At P35, we observed a fourfold increase in dividing cells in stimulated (ipsilateral) M2 compared with manipulated WT littermate controls (7368 ± 1228 versus 1940 ± 512 cells; n = 3 mice per group; P < 0.001) (Fig. 1C). Dividing cells, outside the immediate area of optical fiber placement in layer I, were found in the deep cortical layers near the optogenetically stimulated neurons and in the subcortical fibers of the corpus callosum (Figs. 1B and 2).

To characterize the cells proliferating in response to neuronal activity, we employed immunofluorescence staining for cell identity markers (Fig. 1, D and E, and fig. S1). We found that 54% of the dividing cells in optogenetically stimulated Thy1::ChR2 M2 express the oligodendroglial lineage marker Olig2; stimulated M2 in Thy1::ChR2 mice exhibited a significant increase in dividing Olig2+ cells compared with WT controls (4032 ± 832 versus 519 ± 152 cells, respectively; P < 0.001) (Fig. 1D). Of the dividing cells, 24.5% were PDGFRα+ OPCs (PDGFR, platelet-derived growth factor receptor) (Fig. 1E); a similar number of EdU-marked OPCs was detected by co-labeling with Sox2 and Olig2 (fig. S1B). A
significant increase in EdU-marked Sox2+ neural precursor cells (NPCs) (26) was also observed in stimulated M2 compared to WT controls (fig. S1A). No significant fraction of the proliferating cells represented GFAP+ (GFAP, glial fibrillary acidic protein) or S100β+ astrocytes (fig. S1, C and D). Consistent with reports that optogenetic stimulation of ChR2-expressing neurons within the parameters used here does not induce neuronal injury or death (21), cleaved caspase-3 staining, indicating apoptotic cells, was not observed within optogenetically stimulated M2 (fig. S2).

We also observed an increase in proliferation in the corpus callosum of Thy1::ChR2 mice compared with manipulated WT controls (Fig. 2). Though EdU labeling was observed throughout the corpus callosum, a defined region subjacent to motor cortex and distant from the ventricular region was quantified to avoid the potential confound of EdU+ cells arising from the periventricular-subventricular zone which contains a briskly mitotic and migratory population of cells that take up the EdU marker but may be distinct from those cells responding to neuronal activity (Fig. 2A). Total EdU+ cell quantification revealed a twofold increase in dividing cells in the stimulated Thy1::ChR2 animals compared with manipulated WT controls (2447 ± 174 versus 916 ± 77 cells; n = 3 per group; P < 0.0001) (Fig. 2, B and C), with a significant increase in EdU-marked Olig2+ oligodendroglial lineage cells in the stimulated Thy1::ChR2 mice compared with manipulated WT controls (1016 ± 68 versus 455 ± 58 cells; n = 3 per group; P < 0.0001) (Fig. 2D). Similar to M2, approximately half (42%) of the dividing cells were Olig2+ (Fig. 2D), and no EdU-labeled GFAP+ astrocytes or EdU-labeled S100β+ astrocytes were found.

Optogenetic stimulation of opsin-expressing neurons in the motor cortex elicits expected electrophysiological and behavioral responses (19, 20), but one cannot exclude the possibility of decreased neuronal health due to the presence of the opsin or to the optogenetic stimulation of firing. To control for the effects of pathological neuronal activity, we induced generalized tonic-clonic motor seizures optogenetically using the same frequency and intensity of stimulation but placing the optical fiber more medially in M2 so that light stimulates both motor cortices simultaneously. Proliferation comparable to that seen in the manipulated WT control animals was observed in the seizure animals (Fig. 1C), but not to the degree seen in animals after optogenetic stimulation that results in complex motor behavioral output (n = 3; P < 0.001) (Fig. 1, C to E). That optogenetically induced motor seizures did not elicit a proliferative response of the same magnitude indicates that pathological neuronal activity is not sufficient to account for the observed proliferative effect. Taken together, these findings show that moderate, precisely timed levels of electrical activity in neurons evoking naturalistic behavior in awake, freely behaving mice promoted the proliferation of NPC and OPC populations.

**Evaluation of Inflammatory Response to Fiber Optic Manipulation**

Given the effects of microglial inflammation on NPC (27–29) and OPC (25) proliferation and...
Neuronal Activity–Regulated Oligodendrocyte Differentiation

To define the population dynamics and fate of cells dividing in response to neuronal activity, we repeated the above experiment but sacrificed P35 mice at 24 hours after a single session of optogenetic stimulation and, in a parallel cohort, sacrificed at 4 weeks after a 7-day stimulation paradigm (cycles of 30 s on, 2 min off over 10 min each day, resulting in 2.5 min of total stimulation daily). In Thy1::ChR2 mice, we observed no statistically significant change in the total number of EdU+ cells from 3 to 24 hours, and only 1 to 2% of EdU+ cells colabeled with either Ki67 or cleaved caspase-3 at 24 hours, indicating that the dividing cells cease proliferation soon after stimulated neuronal activity and survive in the subacute time period (n = 3) (Fig. 4, A and B). In contrast, 32% of the EdU+ cells in WT animals remained in a proliferative state at 24 hours, evidenced by the number of EdU-marked activated microglia throughout the M2 cortex in Thy1::ChR2 and WT littermate control mice. Mice in whom seizures were induced and compared to manipulated WT controls (Fig. 3D). To be conservative, n.s. (not significant) indicates the microglial response must be similar to the seizure control animals (n = 3) (Fig. 3D). By 24 hours, EdU-marked, Iba1+ and CD68+ activated microglia were significantly decreased in the premotor cortex compared with the 3-hour time point (191 ± 177 versus 1412 ±777 cells; P < 0.05) (Fig. 3D). Seizure animals exhibited an equivalent number of EdU-marked, Iba1+ and CD68+ microglia compared to Thy1::ChR2 mice in whom locomotion was induced and compared to manipulated WT controls (Fig. 3D). By 24 hours, EdU-marked, Iba1+ and CD68+ activated microglia were significantly decreased in the premotor cortex compared with the 3-hour time point (191 ± 177 versus 1412 ± 777 cells; P < 0.05) (Fig. 3D). There was no difference in the numbers of EdU-marked, Iba1+ and CD68+ activated microglia in stimulated Thy1::ChR2 compared to manipulated WT mice at 24 hours (801 ± 181 versus 515 ± 147 cells; n = 3; P = 0.07) (Fig. 3D). The overall density (EdU+ and EdU−) of activated Iba1+ and CD68+ microglia was also not different between Thy1::ChR2 and WT at 3 or 24 hours, indicating an equal microglial inflammatory response in manipulated Thy1::ChR2 and WT littermate control mice (P > 0.25 in all comparisons) (Fig. 3E). In the corpus callosum, no EdU-marked, CD68− activated microglia were detected in either stimulated (or unstimulated) Thy1::ChR2 or WT mice (Fig. 2, B and E). The microglial inflammatory response was also evaluated after a 7-day stimulation paradigm (cycles of 30 s on, 2 min off over 10 min each day; see below). The overall density (EdU+ and EdU−) of activated Iba1+ and CD68+ microglia was also not different between Thy1::ChR2 and WT on day 7 of or 4 weeks after this 7-day stimulation paradigm (Fig. 3F). The microglial inflammatory response, predominantly localized to the superficial cortex, is thus equal in Thy1::ChR2 mice compared to WT littermate controls after optical fiber placement and blue light stimulation in this model.
colocalization with Ki67 (n = 3; P < 0.05) (Fig. 4B). Thy1::ChR2 mice have fewer EdU+ cells present in M2 at 4 weeks, which may be due to cell dispersion and death during that interval (n = 7 per group) (Fig. 4A and fig. S3A).

Dividing cells were localized to the motor cortex and subcortical white matter, including the corpus callosum, 3 hours after neuronal activity (Figs. 1B and 2). By 4 weeks, dispersion of EdU+ cells was observed (fig. S3A), but no significant increase in EdU+ cells was observed in the corresponding corticospinal tract at the level of the cervical spinal cord compared to the contralateral side (n = 4 Thy1::ChR2; P = 0.48) or to WT (n = 3 WT; P = 0.16) (fig. S3, B and C). This localization may reflect differences inherent in cortical OPCs compared with those found in the deep white matter (34, 35), proximity to neuronal cell bodies (36), or differences in neuronal cell types (e.g., callosal projection neurons versus corticofugal projection neurons).

Because changes in the epigenetic landscape of NPCs and OPCs are necessary for progression to differentiated states (37, 38), we examined population-level changes in histone modifications (Fig. 4, C and D). We found a neuronal activity–regulated increase in trimethylation of histone H3 lysine 9 (inducitive of a repressive, heterochromatin state; P < 0.05) and a concomitant decrease in acetylated histone H3 (correlating with activating regulatory elements; P < 0.05) in dividing (EdU+) cells between 3 and 24 hours after optogenetically stimulated neuronal activity in Thy1::ChR2 mice (Fig. 4, C and D). Thus, neuronal activity promotes a transition to a repressive chromatin state consistent with differentiation.

To evaluate the fate of the cells proliferating in response to neuronal activity, we optogenetically stimulated M2 daily as above for 7 days, then sacrificed mice 4 weeks after the end of stimulation (n = 7 per group). In stimulated M2, we found the absolute number of newly generated (EdU+) Sox2+;Olig2+ NPCs and oligodendroglial (Olig2+) cells remained increased compared with manipulated WT controls (P < 0.05 for NPCs; P < 0.01 for Olig2+) (fig. S4 and Fig. 5A). Neuronal activity–regulated oligodendrogenesis is evidenced by an increase in the number of both EdU+ early oligodendroglial cells expressing transcription factor Olig1 in a nuclear pattern (Olig1nuclear+) and in EdU+ mature oligodendrocytes expressing Olig1 in a perinuclear pattern (Olig1perinuclear+) compared with manipulated WT controls (P < 0.05 for nuclear Olig1 and P < 0.05 for perinuclear Olig1) (Fig. 5, C and D) (39). Neuronal activity–regulated oligodendrogenesis was confirmed using CC1, also a marker for mature oligodendrocytes (534 ± 131 versus 39 ± 30 EdU+/CC1+ cells; n = 4 Thy1::ChR2 mice, 3 WT mice; P < 0.01) (Fig. 5, E and F). Supporting the interpretation that the cells dividing in response to neuronal activity had differentiated into oligodendrocytes, the EdU+ OPC population (EdU+/PDGFRα and EdU+/Sox2+/Olig2+) had diminished compared with the acute time point (Fig. 5B and fig. S4B) concomitantly with the appearance of EdU+ oligodendrocytes (Fig. 5, C to F). An increase in newly generated oligodendrocytes was also found in the corpus callosum of optogenetically stimulated Thy1::ChR2 mice as compared with identically manipulated WT littermate controls (162 ± 39 versus 36 ± 19 EdU+/CC1+ cells; n = 4 Thy1::ChR2 mice, 3 WT mice; P < 0.05) (Fig. 2F). These results demonstrate activity-regulated oligodendrogenesis within the active neural circuit.

Histone deacetylation is required for oligodendrogenesis differentiation (37, 38). Blockade of histone deacetylation with trichostatin A (TSA), an inhibitor of histone deacetylases (HDACs) 1 and 2, prevented mature oligodendrocyte production assessed with Olig1nuclear and CC1 markers (n = 4 per group; P = 0.49 for Olig1nuclear and P = 0.44 for CC1) (Fig. 5, C to F). TSA administration had no effect on the total number of EdU-labeled cells detected at 4 weeks after stimulation (P = 0.3) (fig. S5). Consistent with epigenetic blockade of differentiation, an increase in the number of EdU-labeled, Olig1nuclear+ cells representing immature oligodendrocytes was observed at 4 weeks after stimulation (P < 0.01) (Fig. 5D).

**Response of Oligodendroglial Lineage Cells to Neuronal Activity in Adults**

Using the same model, we evaluated the effect of neuronal activity on oligodendroglial lineage cells in adult animals. At 4 weeks after the 7-day paradigm of optogenetic stimulation (commencing at age P84), we found a twofold increase in the total number of EdU-marked cells in the stimulated M2 compared with manipulated WT controls (2306 ± 337 versus 983 ± 382 cells; n = 4

---

**Fig. 4. Neuronal activity initiates differentiation.** (A) Total number of EdU+ cells in Thy1::ChR2 and WT mice at 24 hours (n = 4 per group) and 4 weeks (n = 7 per group) poststimulation. (B to D) Representative confocal micrographs illustrating colocalization of EdU (red) with markers (green) of cell mitosis (Ki67), apoptosis (cleaved caspase-3), or histone modification markers histone H3 lysine 9 trimethylation (H3K9me3) and histone H3 acetylation (AcH3). In all graphs, red bars indicate Thy1::ChR2 mice; blue bars denote identically manipulated WT littermate controls. *P < 0.05, **P < 0.01, ***P < 0.001. n.s. denotes P > 0.05. Error bars indicate SEM. Scale bars, 10 μm. Value of (—) over x axis = 0 ± 0.
above, we examined the expression of the myelin sheath relative to axon caliber (i.e., g-ratio) can have a profound effect on impulse conduction speed (40). To ascertain the effect of neuronal activity on myelin thickness, we used transmission electron microscopy (TEM) to analyze myelin sheaths in M2 layer VI and subcortical fibers entering the corpus callosum 4 weeks after optogenetic stimulation (Fig. 6A). Relative to axonal diameter (g-ratio = axon diameter/axon + myelin sheath diameter), myelin sheaths were thicker (i.e., decreased g-ratio) in optogenetically stimulated M2 and subcortical fibers (g = 0.701 ± 0.014; n = 4 mice) compared with manipulated WT controls (g = 0.756 ± 0.003; n = 3 mice; P < 0.05) (Fig. 6B). No difference in g-ratio was observed between genotypes on the side contralateral to stimulation (P = 0.13) (Fig. 6C). Quantification of g-ratios was performed by two independent blinded raters.

As supportive evidence to the TEM studies above, we examined the expression of the myelin-related protein myelin basic protein (MBP). Whereas MBP expression levels do not necessarily indicate the formation of compact myelin, as premyelinating oligodendrocytes express MBP, we found that MBP expression was also increased within M2 and subcortical white matter at 4 weeks after optogenetically stimulated neuronal activity, which is consistent with the TEM data above (n = 10 Thy1::ChR2, n = 9 WT; P < 0.001) (fig. S9).

**Behavioral Consequences**

To evaluate possible functional consequences of neuronal activity–regulated oligodendrogenesis and myelination, we tested motor behavioral performance using CatWalk gait analysis 4 weeks after the 7-day stimulation paradigm. Because demyelination or other injury to the motor system impairs limb swing speed, we hypothesized that increased myelination would result in improvement of the sensitive measure of limb swing speed (41). The CatWalk gait analysis test does not require any prior training. CatWalk gait analysis (Fig. 7A) indicated improvement in swing speed of the correlate (left) forelimb during normal gait (interlimb variation +4.8 ± 1.4 cm/s in Thy1::ChR2 mice versus -4.3 ± 1.7 cm/s in WT mice; n = 5 Thy1::ChR2,

---

**Fig. 5. Neuronal activity promotes oligodendrogenesis.** Thy1::ChR2 and WT optogenetically stimulated mice sacrificed 4 weeks after a 7-day stimulation paradigm (P35 to P42) with n = 4 Thy1::ChR2 and 3 WT) or without (n = 7 per group) exposure to TSA (10 mg/kg). **(A to F)** Cell identity markers of EdU-marked surviving cells quantified in the M2 cortex reveal that the majority of the remaining EdU+ cells are in the oligodendrogial lineage (Olig2+, (A)), with diminution of the oligodendrocyte precursor cell (PDGF-Ra) population (B) and concomitant appearance of EdU+ immature oligodendrocytes [Olig; nuclear Olig1+, red and dark blue bars] and mature oligodendrocytes marked by perinuclear Olig1+ ([C and D], pink and light blue bars) and CC1 (E and F). (C and D) Representative confocal micrographs illustrating colocalization of EdU (red) with perinuclear Olig1+ [green (C)] or CC1 [green (E)]. Scale bars, 10 μm. (D and F) Administration of the histone deacetylase inhibitor TSA during the week of optogenetic stimulation results in a blockade of mature oligodendrogenesis. TSA-treated groups are shown on the right halves of these graphs. Increased numbers of immature (Olig1+ cells in the TSA group are consistent with an epigenetic blockade of precursor differentiation. In all graphs, red or pink bars indicate Thy1::ChR2 mice; blue bars denote identically manipulated WT littermate controls. **P < 0.05, **P < 0.01, ***P < 0.001. n.s. represents P > 0.05. Error bars indicate SEM. Value of (——) over x axis = 0 ± 0.
n = 9 WT; P < 0.05) (Fig. 7B), with no change in other parameters of gait such as forepaw strike intensity or stride length (Fig. 7, C and D). There was no effect of genotype on swing speed symmetry (interlimb variation for unmanipulated mice = 1.8 ± 4.0 cm/s versus 1.2 ± 3.2 cm/s; n = 6 Thy1::ChR2, n = 6 WT, respectively; P = 0.58).

Thus, oligodendrogenesis and increased myelin thickness in response to neuronal excitation correlates with altered motor function 4 weeks later.

**Necessity of Myelin Changes**

Do changes in myelin-forming cells account for the observed behavioral improvement? Neuronal activity could affect multiple parameters beyond oligodendrogenesis and myelination that are relevant to behavioral performance in the active circuit. One possibility is that asymmetric walking behavior led to asymmetric muscle development. However, we found that muscle mass and mean fiber diameter of the triceps and biceps brachii were unaffected by our protocol (n = 4 per group; P > 0.5) (fig. S10).

Whereas muscle structure remains unaltered by the optogenetic stimulation paradigm, other activity-dependent changes in the motor circuit such as subtle alterations in synaptic strength could account for the observed behavioral improvement. To address this question, we used HDAC inhibition with TSA, a manipulation that would be expected to enhance synaptic plasticity (42, 43) but to block oligodendrogenesis (37, 38), reasoning that preventing the behavioral improvement in this context would argue for the necessity of activity-induced changes in myelin-forming cells. We thus blocked oligodendrogenesis to determine if it was necessary for the increase in correlate limb swing speed. We administered TSA concomitantly with optogenetic stimulation at P35 to block oligodendrogenesis epigenetically and measured both myelination by TEM and gait performance on the CatWalk 4 weeks post stimulation. TSA administration effectively blocked oligodendrogenesis (n = 4 Thy1::ChR2, n = 3 WT; P < 0.05) (Fig. 5, D and F) and blocked the effect of neuronal activity on myelination (g-ratio = 0.756 ± 0.009 stimulated, TSA-treated Thy1::ChR2 versus 0.762 ± 0.008 in manipulated TSA-treated WT; n = 3 per group; P = 0.62) (Fig. 6D). The observed effect on myelin thickness could be due to HDAC inhibitor-mediated blockade of new oligodendrocyte differentiation or to effects of TSA on existing oligodendrocytes. Blockade of activity-regulated oligodendrogenesis and myelination prevented the behavioral effect (n = 6 Thy1::ChR2, n = 5 WT; P = 0.67) (Fig. 7B). TSA administration did not affect baseline behavior or other parameters of gait (Fig. 7, C and D). As noted above, HDAC inhibition will affect many cell types, and an important consideration is whether TSA administration could itself negatively modulate motor function by effects on neurons or synaptic function. To the contrary, HDAC inhibition has been shown to improve learning and synaptic plasticity (42, 43), so effects of TSA on neuronal plasticity or function would not be expected to account for the blockade of improvement in motor function. These findings support the interpretation that oligodendrocyte differentiation and/or myelination are necessary for the motor behavioral improvement observed after neuronal activity in this model.

**Discussion**

The results presented here demonstrate that behaviorally relevant neuronal activity in layer V projection neurons of the premotor cortex elicits a brisk proliferative response from NPCs and OPCs in the deep layers of the cortex and subcortical white matter, a subset of which differentiate into mature oligodendrocytes that persist weeks after the cessation of stimulation. Myelin thickness increases within the active circuit. These changes in myelin and myelin-forming cells are associated with an improvement in behavioral function that can be blocked by inhibition of oligodendrocyte differentiation and myelination. Taken together, these findings illustrate the plastic nature of myelin in the mammalian brain, raising numerous conceptual and mechanistic questions.

Whereas the present study provides evidence that active neurons influence OPC proliferation, differentiation, and myelination, the relation between these three aspects of myelin formation may not be linear or simple. Hughes et al. have demonstrated that OPCs can differentiate directly into oligodendrocytes without dividing and that OPC proliferation may occur in response to the decision to differentiate by a neighboring OPC (24). In the present study, those OPCs that differentiate without first proliferating would not be expected to account for the increase in myelination observed after neuronal activity in this model.

**Fig. 6. Neuronal activity increases myelin thickness.** (A) Transmission electron microscopy was performed in the projections from the premotor cortex entering the corpus callosum at the level indicated (red box). A representative TEM image of a myelinated axon at this level ipsilateral to optogenetic stimulation is shown at right (8000x, scale bar, 200 nm). (B to D) Scatter plots of g-ratio as a function of axon caliber in the cortical and subcortical projections from the ipsilateral (B) and contralateral (C) M2 in Thy1::ChR2 (n = 4 mice) and WT (n = 3 mice). Black squares, Thy1::ChR2; red circles, WT. (D) Scatter plot of g-ratios in TSA-treated Thy1::ChR2 (black squares; n = 3 mice) and WT (red circles; n = 3 mice) ipsilateral to stimulation. n.s. represents P > 0.05. Error bars indicate SEM.
have been underestimated. Similarly, whereas Young et al. have recently shown that adult-born oligodendrocytes contribute to ongoing myelin remodeling (44), it is not yet clear exactly how this occurs. In the present study, we cannot distinguish between the possibilities that neuronal activity results in myelination of previously unmethylated axons, that new oligodendrocytes incorporate into existing sheaths, or that existing oligodendrocytes increase the thickness of the sheath. It is also interesting to note the difference in magnitude of the robust OPC proliferative response and new oligodendrocyte generation compared with the relatively small magnitude of change in myelin thickness (−10% change in average g-ratio), suggesting an alternative fate for some of these cells.

The paradigm used here mimics practicing a complex motor task. Would volitional, repetitive execution of a complex motor task result in the same findings? Neuroimaging studies suggest that this would be the case. A diffusion tensor imaging (DTI) study of humans before and after a 6-week period of practicing a new complex visuo-motor task (juggling) revealed changes in the microstructure of subcortical white matter within a brain region active in the task (45). Similarly, training in a complex motor task involving one limb was correlated with DTI-based indication of more developed white matter microstructure in the corpus callosum subjacent to the correlate motor cortex, precisely in the same location in which we observed activity-regulated oligoden- drogenesis and increased thickness of myelin sheaths (46). The degree of complexity, directionality, or repetition necessary to elicit changes in myelin microstructure is not clear. Thus, wandering around a cage may not focally alter motor circuit myelin, but repeated episodes of a specific motor task (e.g., walking in a counterclockwise circle) may elicit a response in the relevant neural circuit that facilitates that behavior subsequently. Conversely, would hypoactivity of a circuit result in thinner myelin? Elegant studies evaluating the effects of social isolation on myelin thickness in the medial prefrontal cortex, a region important in social function, suggest that this, too, may be the case (47, 48).

It may be that neuronal activity–regulated changes in myelin-forming cells are most relevant to cortical and association fiber myelin. We observed the proliferative response in the deep layers of the cortex and subcortical projections, including those in the corpus callosum projecting to the contralateral motor area, but not those in deep white-matter projections down the corticospinal tract. Similarly, the aforementioned DTI study of white-matter changes after training in a complex visuo-motor task revealed alterations in myelin microstructure consistent with improved myelination within the subcortical association fibers underlying the intraparietal sulcus (45). Regional differences may exist in the response of myelin-forming cells to neuronal activity that may reflect differences inherent in cortical OPCs compared with those found in the deep white matter; cortical OPCs have a distinct developmental origin (34), respond differentially to mitogens (35), appear to contribute particularly to the pathogenesis of glial tumors (49), and may respond differentially to activity-regulated signals. Alternatively, the localization of the observed effect on OPC proliferation and differentiation may reflect proximity to the neuronal cell bodies, as OPC mitogens can be released from the neuronal soma rather than from axons (36). A third possibility is that specific neuronal types (e.g., callosal neurons compared to corticofugal neurons) may interact differentially with myelin-forming cells.

How would small or localized changes in myelin structure affect neural circuit function? Subtle g-ratio changes in the 0.6-to-0.8 range can result in substantial changes in conduction velocity (40). Neural circuit function is complex and incompletely understood, but some prominent models of cortical performance (50) invoke the need for activity-dependent myelination as a means of balancing conductance delay and synaptic strength parameters (see (51) for a recent review). It should be noted, however, that maladaptive changes in conduction delay could conversely result in perturbation of neural function by disrupting neuronal signal synchrony.

The present study may elucidate the mechanistic role of experience in brain development, defining activity-dependent adaptive changes in myelin as a dimension along which experience modulates neural function. Adult-born oligodendrocytes contribute to myelin remodeling throughout life (44), sensory deprivation via social isolation results in hypomyelination of the prefrontal cortex of mice (47, 48), and learning a new language (52) or complex motor tasks (45) have been shown to alter white-matter structure within the relevant neural circuits in humans. These studies imply the dynamic nature of cerebral myelin throughout life and the role experience may have in modulation of the brain’s infrastructure. The data presented here demonstrate that the effect of experience on myelinated fiber microstructure may result from direct effects of neuronal activity on myelin-forming cells.

The potent effects of neuronal activity on OPC proliferation, oligodendrogenesis, and myelination could have broad clinical implications. When dysregulated, neuronal activity–induced OPC proliferation may play a role in glioma pathogenesis, given that OPCs are thought to be the cell of origin for multiple subtypes of high-grade glioma in both children and adults (49, 53). Pediatric high-grade gliomas appear linked to epigenetic dysregulation caused by driver mutations.

**Fig. 7.** Activity-regulated oligodendrogenesis and myelin remodeling correlate with improved behavioral function. CatWalk gait analysis was used to evaluate motor performance during normal gait 4 weeks after the stimulation paradigm described above. (A) Schematic of the CatWalk apparatus. Experimental mice walk through a long, narrow corridor on a touch-sensitive glass platform, under which a digital camera records paw print contours, allowing for software-guided reconstruction and analysis of gait. LF, left forepaw; LH, left hindpaw; RF, right forepaw; RH, right hindpaw. (B) Interlimb forepaw swing speed (in centimeters per second) difference of left forelimb minus right forelimb (n = 5 Thy1::ChR2 and 9 WT; n = 6 TSA-treated Thy1::ChR2 and 5 TSA-treated WT). (C and D) No alterations to paw pressure (C) or stride length (D) were observed in optogenetically stimulated Thy1::ChR2 mice or their WT littermate controls. The same is true in animals treated with the histone deacetylase inhibitor TSA (C and D). Untreated: n = 5 Thy1::ChR2 mice and 9 WT mice; TSA-treated: n = 4 Thy1::ChR2 mice and 5 WT mice. n.s. denotes P > 0.05. *P < 0.05. Error bars indicate SEM. AU, arbitrary units.
in histone H3 that may prevent effective control of such proliferation (54, 55). Conversely, precisely harnessing the myelinogenic potential of neuronal-OPC interactions could yield effective regenerative strategies in diseases of myelin.

**Materials and Methods**

**Statistical Analysis**

For total EdU counts, cell identity counts, muscle morphometry analyses, and CatWalk behavioral tests (swing speed, forepaw intensity measurements, and stride length), group mean differences were assessed using two-way analysis of variance (two-way ANOVA) with Tukey or Tukey-Kramer post-hoc tests to further examine pairwise differences. Paired, two-tailed Student’s t tests were used for analysis of mean differences between the ipsilateral and contralateral sides within the same animal in MBP intensity analyses. Unpaired, two-tailed Student’s t tests were used for analysis of mean differences between animals in electron microscopy measurements. A level of P < 0.05 was used to designate significant differences.

As determined before data collection, animals were excluded from analysis if optogenetic stimulation did not result in the expected ambulation behavior (for Thy1::ChR2 animals) or, in the case of behavioral analysis, if the animal did not complete four successful runs characterized by variation under 60%, lasting no more than 5 s, and consistent movement along the CatWalk apparatus.

**Mice and Housing Conditions**

Male Thy1::ChR2 (The Jackson Laboratory, line 20) mice were bred with female CD1 mice (Charles River Laboratories). All experiments were performed on animals either heterozygous for Thy1::ChR2 or WT littersmates housed in a 12-hour light/dark cycle with unrestricted access to food and water. Animals were housed five per cage. Male animals were used for the behavioral analysis, and both sexes were used equally for all other studies. No animals were manipulated other than as reported for that experimental group; that is, there was no history of drug exposures, surgeries, or behavioral testing for the animals used other than that reported for the given experimental group. All procedures were performed in accordance with guidelines set in place by the Stanford University Institutional Care and Use Committee.

**Fiber Optic Placement and in Vivo Optogenetic Stimulation**

On P32 or P33, animals were anesthetized with 1 to 4% isoflurane and placed in a stereotactic apparatus. After aseptically preparing the skin, the skull was exposed using a midline incision, and a dental drill with a 0.5-mm burr was used to expose the brain. A fiber optic ferrule (Doric Lenses) was placed over the premotor cortex (M2) and secured with dental cement. Ferrules were implanted at the following coordinates: ~0.5 mm lateral to midline, 1.0 mm anterior to bregma, and ~0.6 mm from the skull in the right hemisphere [as described in (56)]. On P35, all freely moving animals were connected to a 100-mW 473-nm diode-pumped solid-state laser system with a monofiber patch cord, and pulses of light were administered at 20 Hz. Approximately 3.7 V at 20 Hz (50-ms pulse length; 25 ms on/25 ms off) produced an output of ~1 mW, which is the minimum intensity necessary to initiate the unidirectional circling behavior of the mice. The blue light from the laser penetrates ~0.5 mm from the tip of the optical fiber and stimulates the apical dendrites of cortical layer V neurons expressing the ChR2 opsin. M2 layer Voutput neurons project to the M1 motor cortex (which, in turn, projects down the corticospinal tract) and also to the contralateral motor cortex via the corpus callosum. For acute (3-hour) and subacute (24-hour) time points, light was administered during a 30-min session, with alternating 30-s light exposures and 2-min recovery periods, and mice were sacrificed either 3 or 24 hours, respectively, after the start of the stimulation session. For the long-term time point (4 weeks), animals were exposed to the same alternating light exposure paradigm (30 seconds on/2 min off) for 10 min per day for 7 days beginning at P35 or P84 and sacrificed 4 weeks after the cessation of the 7-day stimulation paradigm. For the 7-day time point, P29 mice were stimulated according to the stimulation protocol used for the 4-week time point but were sacrificed 3 hours after the final stimulation session on day 7 at P35. For all stimulation sessions, all animals were given an intraperitoneal injection of EdU (40 mg/kg). To control for stimulation in the analysis of the corpus callosum, a separate group of unstimulated mice were used. In unstimulated mice, animals underwent surgery, ferrule–fiber optic implantation, and EdU injections as described above but were not exposed to 20-Hz pulses of blue light. In animals treated with a histone deacetylase inhibitor, mice were given an intraperitoneal injection of TSA (Selleck Chemicals, 10 mg/kg) concurrent with EdU administration. When the ferrule is properly placed over right M2, Thy1::ChR2 animals respond with increased locomotor behavior (circling) to the left (movie S1), whereas WT animals have no change in behavioral output.

To induce seizures without circling behavior, the ferrule was placed slightly more medially in M2 (~0.25 mm lateral to midline), with no change in stimulation intensity or frequency. Animals exhibited obvious motor seizure activity (tonic-clonic movements) of ~10 s in duration; at the onset of tonic-clonic movements the stimulation was held (blue light off), and animals were allowed to recover to behavioral baseline before further stimulation within the 30-min stimulation session. Animals had an average of 5 to 10 brief seizures, lasting 10 to 15 s each, during the single stimulation session and were sacrificed 3 hours later.

**Perfusion and Immunohistochemistry**

All animals were anesthetized with avertin and transcardially perfused with 15 ml phosphate-buffered saline (PBS). Brains were postfixed in 4% paraformaldehyde (PFA) overnight at 4°C before cryoprotection in 30% sucrose. Brains were embedded in optimum cutting temperature (OCT) (Tissue-Tek) and sectioned in the coronal plane at 40 µm using a sliding microtome (Leica, HM450). Spinal cords were dissected from the column and allowed to equilibrate in 30% sucrose. From each cord, transverse segments 3 mm in length were isolated and embedded in OCT, and a series of 40-µm transverse sections was collected using a sliding microtome (Leica, HM450). For immunohistochemistry, sections were stained using the Click-It EdU cell proliferation kit and protocol (Invitrogen) to expose EdU labeling followed by incubation in blocking solution [3% normal donkey serum, 0.3% Triton X-100 in tris-buffered saline (TBS)] at room temperature for 1 hour. Goat antibody to Sox2 (anti-Sox2) (1:50; R&D Systems AF2018), rabbit anti-Olig2 (1:500; Millipore AB96610), goat anti-PDGFRα (1:500; R&D Systems AF1062), rabbit anti-Iba1 (1:2000; Wako 019-19741), rat anti-CD68 (1:200; Abcam AB53444), rabbit anti-GFAP (1:500; Dako Z0334), rabbit anti-Ki67 (1:500; Abcam AB155580), rabbit anti– caspase-3 (1:500; Cell Signaling 9662), rabbit anti-Olig1 (1:500; a generous gift from Dr. Charles Stiles), rabbit anti-histone H3K9me3 (trimethyl K9; 1:200; Abcam AB88998), rabbit anti-acetyl-histone H3 (1:200; Millipore 06-599), goat anti–cFos (1:500; Abcam AB7655), chicken anti–MAP2 (1:10,000; Abcam AB5392), mouse anti–CC1 (1:20; Calbiochem OP80), rabbit anti–S100β (100μg/ml; Sigma S2644), or rat anti–MBP (1:200; Abcam AB73349) were diluted in 1% blocking solution (normal donkey serum in 0.3% Triton X-100 in TBS) and incubated overnight at 4°C, with the exception of the anti–CC1 antibody for which a 1-week incubation was used. All antibodies have been validated in the literature and/or in Antibodypedia for use in mouse immunohistochemistry. To further validate the antibodies in our hands, we confirmed that each antibody stained in the expected cellular patterns and brain-wide distributions (e.g., nuclear Sox2 staining in the subventricular zone). For the case of cleaved caspase-3 staining, we confirmed antibody staining in ischemic brain tissue as a positive control. Secondary-only stains were performed as negative controls.

The following day, sections were rinsed three times in 1X TBS and incubated in secondary antibody solution (1:500) and 4',6-diamidino-2-phenylindole (1:1000) in 1% blocking solution at 4°C overnight. The following secondary antibodies were used: DyLight 405 donkey anti-rabbit (Jackson ImmunoResearch), Alexa 488 donkey anti-goat (Jackson ImmunoResearch), FITC donkey anti-rabbit (Jackson ImmunoResearch), FITC donkey anti-rat (Jackson ImmunoResearch), Alexa 647 donkey anti-chicken (Jackson ImmunoResearch), Alexa 647 donkey anti-mouse (Invitrogen), or Alexa 647 donkey anti-goat (Invitrogen). The next day, sections were rinsed three times in TBS and mounted with Krystalon (HARLECO) mounting medium.
**Confocal imaging and Quantification**

All cell counting was performed by experimenters blinded to the experimental conditions using a Zeiss LSM700 scanning confocal microscope (Carl Zeiss). For EdU stereology, all EdU-labeled cells in every 12th bilateral (ipsilateral and contralateral to fiber optic ferrule) section (or every 6th for the 4-week–time-point tissue) throughout the extent of M2 or the corpus callosum were counted by blinded experimenters at 200× or 400× magnification, excluding those cells in the outermost field of focus (i.e., the edge of the section), as well as those within 100 µm surrounding ferrule-induced tissue damage. The total number of EdU-labeled cells per M2 or corpus callosum was determined by multiplying the number of EdU cells by 12 or 6 for the 4-week time point. For each animal, 50 to 100 EdU cells for M2 and 15 to 25 EdU cells for the corpus callosum were randomly chosen and assessed for double-labeling with the aforementioned primary antibodies to determine the proportion of EdU cells with specific cell identities or epigenetic markers. A minimum of three animals was assessed for each marker. Cells were considered double-labeled when they colocalized within the same plane. This proportion was then multiplied by the total number of EdU-labeled cells to determine the total number of cells within each M2 hemisphere or corpus callosum for every animal with that specific cell identity. For EdU quantification in the cervical spinal cord, EdU-labeled cells were counted at 200× magnification in representative 40-µm sections within the extent of the dorsal corticospinal tract. For MBP intensity measurements, forebrain sections surrounding the site of the corticospinal tract. For MBP intensity measurements, forebrain sections surrounding the site of the corticospinal tract were collected using a Gatan Orius digital camera. Muscle Histology and Morphometry

Thy1::ChR2 and WT mice were anesthetized with avertin, then perfused with 10 ml PBS followed by 10 ml 2% glutaraldehyde/4% PFA/100-mM sodium cacodylate 4 weeks after the 7-day optogenetic stimulation paradigm. Forelimbs were removed, and biceps and triceps brachii muscles were dissected out bilaterally and weighed with an analytical balance. Whole muscles were embedded in paraffin, sectioned at 5 µm, and stained with hematoxylin and eosin. Blinded morphometric analysis was performed at 400× magnification (SPOT Imaging Solutions) by obtaining the mean of the shortest diameter of all muscle fibers within a single field of view (80 ± 5 fibers), excluding damaged muscles. Myelinated fiber density was analyzed by quantifying the number of myelinated axons per 8000× electron micrograph. An average of 71 such images were quantified per animal, and the average number of myelinated fibers per image was calculated for each animal. We did not find a significant change in the density of myelinated fibers (2.59 ± 0.65 myelinated axons per field in Thy1::ChR2 mice versus 1.88 ± 0.47 myelinated fibers per field in WT mice on the side ipsilateral to optogenetic stimulation; n = 4 Thy1::ChR2 animals and 3 WT animals; P = 0.45). However, this analysis is complicated by the fact that the distribution of projection axons entering the corpus callosum from the motor cortex is shaped like an inverted cone or a funnel in which the same number of axons would appear less dense superiorly at the base of the cone and denser inferiorly at the vertex of the cone. Thus, even micrometer changes in the level of analysis would affect the density of fibers observed. Whereas Thy1::ChR2 and WT mice were sampled in the same way and at the same approximate level, we believe that the variability introduced by the conformation of the structure makes it difficult to detect small changes in myelinated fiber density. Thus, we do not detect pronounced differences, but we cannot exclude small changes in myelinated fiber density after optogenetic stimulation. Behavioral Analysis

To investigate the effect of unilateral optogenetic stimulation of the corticospinal tract on motor output, we used the CatWalk gait analysis system (Noldus, Netherlands). The apparatus consists of a glass walkway with opaque black siding that is internally illuminated with fluorescent lights via one of the long edges of the glass floor. As the mouse traverses the glass floor, the footprints cause the light to be reflected downward and are recorded by a camera positioned underneath the glass and relayed to an adjacent computer. For a detailed description of the CatWalk method, see (41). To ensure consistent running, mice were acclimatized to handling for several weeks before recording, and all tests were run in a dark room. Only male mice were used to reduce variability in output measures between males and females, based on body weight. Animals were tested 4 weeks after the cessation of the 7-day optogenetic stimulation paradigm previously described. Male mice that did not undergo surgery and optogenetic stimulation were used to control for changes in behavior due to experimental manipulation. No behavioral training on the CatWalk apparatus was performed. Behavioral testing was performed during the light cycle. Four successful runs (with success being characterized by variation under...
